**BRUSHLESS ELECTRIC
MOTOR/GENERATOR****RELATED APPLICATIONS**

This application claims the benefit of the filing date of U.S. patent application Ser. No. 14/608,232, entitled "An Improved Brushless Electric Motor/Generator," filed on Jan. 29, 2015. This application also claims the benefit of the filing date of U.S. provisional patent application Ser. No. 62/055,612, entitled "An Improved DC Electric Motor/Generator with Enhanced Permanent Magnetic Flux Densities," filed on Sep. 25, 2014. This application also claims the benefit of the filing date of U.S. provisional patent application Ser. No. 62/055,615, entitled "An Improved DC Electric Motor/Generator with Enhanced Permanent Magnetic Flux Densities," filed on Sep. 25, 2014. This application also claims the benefit of the filing date of U.S. provisional patent application Ser. No. 62/056,389, entitled "An Improved DC Electric Motor/Generator with Enhanced Permanent Magnetic Flux Densities," filed on Sep. 26, 2014. This application is also a continuation-in-part of the commonly owned U.S. application Ser. No. 13/848,048, entitled "An Improved DC Electric Motor/Generator with Enhanced Permanent Magnetic Flux Densities" filed on Mar. 20, 2013, which claims the benefit of U.S. Provisional Application Ser. No. 61/613,022, filed on Mar. 20, 2012. The disclosures of all of the above applications are hereby incorporated by reference for all purposes.

TECHNICAL FIELD

The invention relates in general to a new and improved electric motor/generator, and in particular to an improved system and method for producing rotary motion from a electro-magnetic motor or generating electrical power from a rotary motion input.

BACKGROUND INFORMATION

Electric motors use electrical energy to produce mechanical energy, very typically through the interaction of magnetic fields and current-carrying conductors. The conversion of electrical energy into mechanical energy by electromagnetic means was first demonstrated by the British scientist Michael Faraday in 1821 and later quantified by the work of Hendrik Lorentz.

A magnetic field is generated when electric charge carriers such as electrons move through space or within an electrical conductor. The geometric shapes of the magnetic flux lines produced by moving charge carriers (electric current) are similar to the shapes of the flux lines in an electrostatic field. Magnetic flux passes through most metals with little or no effect, with certain exceptions, notably iron and nickel. These two metals, and alloys and mixtures containing them, are known as ferromagnetic materials because they concentrate magnetic lines of flux. Areas of greatest field strength or flux concentration are known as magnetic poles.

In a traditional electric motor, a central core of tightly wrapped current carrying material creates magnetic poles (known as the rotor) which spins or rotates at high speed between the fixed poles of a magnet (known as the stator) when an electric current is applied. The central core is typically coupled to a shaft which will also rotate with the

2

rotor. The shaft may be used to drive gears and wheels in a rotary machine and/or convert rotational motion into motion in a straight line.

Generators are usually based on the principle of electromagnetic induction, which was discovered by Michael Faraday in 1831. Faraday discovered that when an electrical conducting material (such as copper) is moved through a magnetic field (or vice versa), an electric current will begin to flow through that material. This electromagnetic effect induces voltage or electric current into the moving conductors.

Current power generation devices such as rotary alternator/generators and linear alternators rely on Faraday's discovery to produce power. In fact, rotary generators are essentially very large quantities of wire spinning around the inside of very large magnets. In this situation, the coils of wire are called the armature because they are moving with respect to the stationary magnets (which are called the stators). Typically, the moving component is called the armature and the stationary components are called the stator or stators.

Motors and generators used today produce or utilize a sinusoidal time varying voltage. This waveform is inherent to the operation of these devices.

In most conventional motors, both linear and rotating, enough power of the proper polarity must be pulsed at the right time to supply an opposing (or attracting) force at each pole segment to produce a particular torque. In conventional motors at any given instant only a portion of the coil pole pieces is actively supplying torque.

With conventional motors a pulsed electrical current of sufficient magnitude must be applied to produce a given torque/horsepower. Horsepower output and efficiency then is a function of design, electrical input power plus losses.

With conventional generators, an electrical current is produced when the rotor is rotated. The power generated is a function of flux strength, conductor size, number of pole pieces and speed in RPM. However output is a sinusoidal output which inherently has losses similar to that of conventional electric motors.

Specifically, the pulsed time varying magnetic fields produces undesired effects and losses, i.e. iron hysteresis losses, counter-EMF, inductive kickback, eddy currents, inrush currents, torque ripple, heat losses, cogging, brush losses, high wear in brushed designs, commutation losses and magnetic buffeting of permanent magnets. In many instances, complex controllers are used in place of mechanical commutation to address some of these effects.

Additionally, in motors or generators, some form of energy drives the rotation and/or movement of the rotor. As energy becomes more scarce and expensive, what is needed are more efficient motors and generators to reduce energy consumption, and hence costs.

SUMMARY

In response to these and other problems, there is presented various embodiments disclosed in this application, including methods and systems of increasing flux density by permanent magnet manipulation. Disclosed are various embodiments for a motor/generator comprising: a rotor adapted to rotate about a longitudinal axis, the rotor comprising a first partial toroidal magnetic cylinder defining a semi-circular tunnel, wherein the plurality of magnets forming the first partial toroidal magnetic cylinder have substantially all like poles facing inward toward the semi-circular tunnel, the semi-circular tunnel having an entrance and an exit forming

an open throat defined by a space between the entrance and the exit, and a stator positioned about the longitudinal axis within a rotational path of the rotor.

These and other features, and advantages, will be more clearly understood from the following detailed description taken in conjunction with the accompanying drawings.

It is important to note the drawings are not intended to represent the only aspect of the invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross-sectional view of a toroidal magnetic cylinder illustrating representative “planar” portions of magnetic flux paths within and around the cylinder with an iron core.

FIG. 2a is an isometric and partial section view of a toroidal magnetic cylinder of FIG. 1.

FIG. 2b is a detailed partial isometric section view of the toroidal magnetic cylinder of FIG. 1a illustrating the planar magnetic fields or flux walls generated within the cylinder interior.

FIGS. 3a through 3f are conceptualized views of a rotor or rotor assembly and various components.

FIGS. 4a through 4d are conceptualized views of a coil assembly functioning as a stator.

FIGS. 4e and 4f are conceptualized views of a coil assembly functioning as a rotor.

FIGS. 5a through 5e are conceptualized views of a motor generator assembly combining the rotor and stator.

FIGS. 6a and 6b are conceptualized views of a motor/generator.

FIG. 7a is a communication flow diagram of various exemplary control components of the motor/generator which may be used in various aspects of the disclosed invention.

FIG. 7b is a diagram of a sensor and switching control circuit which may be used in various aspects of the present invention.

FIG. 8a is an isometric view of a flux or magnetic field concentrator which could be used with various embodiments disclosed herein.

FIG. 8b is an isometric view of an improved flux or magnetic field concentrator which could be used with various embodiments disclosed herein.

DETAILED DESCRIPTION

Specific examples of components, signals, messages, protocols, and arrangements are described below to simplify the present disclosure. These are, of course, merely examples and are not intended to limit the invention from that described in the claims. Well-known elements are presented without detailed description in order not to obscure the present invention in unnecessary detail. For the most part, details unnecessary to obtain a complete understanding of the present invention have been omitted inasmuch as such details are within the skills of persons of ordinary skill in the relevant art. Details regarding conventional control circuitry, power supplies, or circuitry used to power certain components or elements described herein are omitted, as such details are within the skills of persons of ordinary skill in the relevant art.

When directions, such as upper, lower, top, bottom, clockwise, or counterclockwise are discussed in this disclosure, such directions are meant to only supply reference directions for the illustrated figures and for orientation of components in the figures. The directions should not be read

to imply actual directions used in any resulting invention or actual use. Under no circumstances, should such directions be read to limit or impart any meaning into the claims.

Most motors and generators used today require or produce a sinusoidal time varying voltage referred to as Alternating Current (AC). When Direct Current is utilized it must first be inverted and pulsed to replicate an AC waveform to produce the desired current or mechanical output. Certain embodiments of the present invention neither produces nor utilizes AC but instead directly produces or utilizes a non sinusoidal Direct Current without the need for rectification or commutation. This results in the elimination of AC losses and results in a more efficient utilization of input or output power. However, certain aspects of the invention may accept any rectified AC current and thus may be “blind” to input power supply phasing. Thus, simple rectified single phase, two phase, three phase power, etc. are all acceptable for input power depending on the configuration.

Turning now to FIG. 1, there is a cross-sectional view of one embodiment of a partial toroidal magnetic cylinder 100 illustrating representative planar magnetic flux paths 101 (illustrating magnetic forces) within and around the partial cylinder. These are representative illustrations; actual flux paths are dependent on the material design and specific configuration of the magnets within the cylinder. In certain embodiments, the partial magnetic cylinder 100 comprises an outer cylinder wall 102 and an inner cylinder wall 104. The outer cylinder wall 102 and inner cylinder wall 104 may be made with a plurality of magnets. In a lateral section view, such as illustrated in FIG. 1, it can be seen that the outer cylinder wall 102 is comprised of a plurality of magnets 106, comprising individual magnets, such as magnets 106a, 106b, 106c, etc. Similarly, the inner cylinder wall 104 may be comprised with a plurality of magnets 108, comprising individual magnets 108a, 108b, etc. It should be noted that only one polarity of the magnets are utilized within (or facing into) the magnetic cylinder or magnet assembly. For instance in the illustrative embodiment of FIG. 1, the north poles of the magnets 106 are each pointing radially towards a center or longitudinal axis 120 (which is coming out of the page in FIG. 1). On the other hand, the north poles of the magnets 108 each point radially away from the center 120 and towards an interior cavity 124 of the partial toroidal magnetic cylinder 100.

In certain embodiments, there may be a central core, such as an iron core 110, where a portion of the iron core 110 is positioned in the interior cavity 124 between the outer wall 102 and the inner wall 104. Although the iron core 110 is used in this embodiment as a magnetic flux line concentrator, other core materials may be used when design considerations such as strength, reduction of eddy currents, cooling channels, etc. are considered. In fact, certain embodiments may not use the central iron core 110.

In certain embodiments, the magnets of the plurality of magnets 106 and magnets 108 may be made of out any suitable magnetic material, such as: neodymium, Alnico alloys, ceramic permanent magnets, or electromagnets. The exact number of magnets or electromagnets will be dependent on the required magnetic field strength or mechanical configuration. The illustrated embodiment is only one way of arranging the magnets, based on certain commercially available magnets. Other arrangements are possible, especially if magnets are manufactured for this specific purpose. One such exemplary embodiment is illustrated with respect to FIGS. 3a-3e.

In the embodiment illustrated in FIG. 1, the partial toroidal magnetic cylinder 100 has two open ends 114 and

116. Thus, an open magnetic space or throat 115 is formed between the open end 114 and the open end 116. As will be explained later, when the partial toroidal magnetic cylinder 100 is used as a rotor, the open magnetic area 115 may include weights to balance the rotor as it turns around the longitudinal axis 120. In yet other embodiments, the weights may be a plurality of filler magnets positioned such that they have magnetic poles which are opposite of the magnetic poles of the magnets forming the partial toroidal magnetic cylinder.

When the plurality of magnets 106 and 108 are arranged into the outer wall 102 and inner wall 104 to form the cylinder 100, the flux lines 101 will form particular patterns as represented in a conceptual manner by the flux lines illustrated in FIG. 1. The actual shape, direction, and orientation of the flux lines 101 depend on factors such as the use of an interior retaining ring, material composition and configuration. For example, the flux line 112a from the magnet 106a of the exterior wall 102 tends to flow from the north pole of the magnet in a perpendicular manner from the face of the magnet into and through the interior cavity 124 of the cylinder 100, through the iron core 110, exiting through the open end 114 into the open area 115, then flow around the exterior of the partial toroidal cylinder 100, and back to an exterior face of the magnet 106a containing its south pole.

Similarly, the flux line 112b from the magnet 106b of the exterior wall 102 tends to flow from the north pole of the magnet in a perpendicular manner from the face of the magnet into and through the interior cavity 124 of the cylinder 100, through the iron core 110, exiting through the open end 114 into the open space 115, then flow around the exterior of the cylinder 100, and back to the face of the magnet 106b containing its south pole. Although only a few flux lines 112 are illustrated for purposes of clarity, each successive magnet in the plurality of magnets will produce similar flux lines. Thus, the magnetic flux forces for each successive magnet in the plurality of magnets 106 tend to follow these illustrative flux lines or patterns 112 for each successive magnetic disc in the plurality of magnets 106 until the magnets at the open ends 114 or 116 of the magnetic cylinder 100 are reached.

Magnets on the opposing side of the cylinder 100, such as magnet 106c tend to generate flux lines 112c from the magnet 106c on the exterior wall 102 which tends to flow from the north pole of the magnet in a perpendicular manner from the face into and through the interior cavity 124 of the cylinder 100, through the iron core 110, exiting through the open end 116 into the open space 115, then flow around the exterior of the cylinder 100, and back to an exterior face of the magnet 106c containing its south pole. Although only a few flux lines 112 are illustrated for purposes of clarity, each successive magnet in the plurality of magnets will produce similar flux lines. As discussed above, in yet other embodiments, the iron core 110 is not necessary. In embodiments without an iron core, the flux lines will generally flow in a similar manner, but may not be as concentrated as embodiments with an iron core. As discussed above, in certain embodiments, the iron core may act as a flux concentrator.

In certain embodiments, the interior magnetic wall 104 also produces flux forces, which may be illustrated by flux lines, such as exemplary flux lines 118. For instance, the flux line 118a from the magnet 108a on the interior wall 104 tends to flow from the north pole in a perpendicular manner from the face of the magnet, into and through the interior cavity 124 of the cylinder 100, through the iron core 110, out

the open end 114 and into the open space 115, then back through the center space 123 formed by the interior wall 104 to the face of the magnet 108a containing its south pole. Similarly, the flux line 118b from the magnet 108b on the interior wall 104 tends to flow from the north pole in a perpendicular manner from the face of the magnet, into and through the interior 124, around the interior wall 104 through the iron core 110, out the open end 116 and into the open space 115, then back through the center space 123 formed by the interior wall 104, then back to the face of the magnet 108b containing its south pole.

The magnetic flux forces for each successive magnet in the plurality of magnets 108 tend to follow these illustrative flux lines or patterns 118 for each successive magnet in the plurality of magnets 108 until the open ends 114 or 116 of the magnetic cylinder 100 are reached. Thus, the flux forces produced by the magnets of the interior wall 104 of the partial cylinder 100 have an unobstructed path to exit through one of the open ends of the cylinder and return to its opposing pole on the exterior or interior of the cylinder.

In some embodiments, the magnetic flux lines 112 and 118 will tend to develop a stacking effect and the configuration of the exterior magnetic cylinder manipulates the flux lines 101 of the magnets in the magnetic cylinder 100 such that most or all of the flux lines 110 flows out of the open ends 114 and 116 of the cylinder 100.

In conventional configurations, the opposing poles of the magnets are usually aligned longitudinally. Thus, the field flux lines will “hug” or closely follow the surface of the magnets. So, when using conventional power generating/utilization equipment, the clearances must usually be extremely tight in order to be able to act on these lines of force. By aligning like magnetic poles radially with respect to the center 120 of the partial cylinder 100, the magnetic flux lines 112 and 118 tend to stack up as they pass through the center of the magnetic cylinder 110 and radiate perpendicularly from the surface of the magnets. This configuration allows for greater tolerances between coils and the magnetic cylinder 100.

In certain embodiments, the iron core 110 is positioned concentrically about the center 120 of the magnetic cylinder 100 such that the iron core is equidistant radially from the interior wall 104, generating a representative flux pattern 101 as illustrated in FIG. 1. The flux fields or lines are drawn to the iron core 110 and are compressed or concentrated as they approach the iron core. The flux fields may then establish what can be visualized as a series of “flux walls” surrounding the iron core which extend throughout the partial cylinder 100 and the exit open ends 114 and 116. Collectively, the partial toroidal magnetic cylinder 100 generates a partially circular magnetic field 125 which is the cumulation of individual flux fields from each magnet. Correspondingly, there will be a throat or an open area 115 generally defined by the area between the open ends 114 and 116 with the angle α . In FIG. 1, the angle α between the open face 114 of the partial magnetic cylinder 110 and the open face 116 is illustrated in FIG. 1 to be approximately 60 degrees. In other embodiments, the angle α may be between 180 degrees to approaching 0 degrees. Obviously, when the angle is at 180 degrees the open area 115 is larger. When the angle approaches zero, the open area 114 is much smaller. The angle α cannot be zero, however, or the magnetic field 125 would collapse upon itself.

As discussed above, FIG. 1 is a two dimensional section view cut at an angle which is transverse to the longitudinal axis 120 (or center axis). In addition to the cylindrical walls 102 and 104, there may also be side walls which are not

shown in FIG. 1. The side walls join the exterior cylindrical wall 102 to the interior cylindrical wall 104. In certain embodiments, the side walls may be made of a plurality of side wall magnets which contribute to the cumulative magnetic field 125.

Turning now to FIG. 2a, there is presented is a conceptual isometric view of the toroidal magnetic cylinder 100 having the central iron core 110 partially positioned within the interior cavity or tunnel 124 of the partial toroidal magnetic cylinder. As illustrated in FIG. 2a, there is the exterior cylindrical wall 102, the interior cylindrical wall 104, a side wall 170, and an opposing side wall 172. In embodiments where the side wall 170 and side wall 172 are formed from a plurality of magnets, each magnet in the plurality of magnets have a common magnetic pole with cylindrical walls 102 and 104 which also face the interior cavity 124. In other embodiments, which will be discussed later, the side wall magnets may be a plurality of wedge shaped magnets specifically sized to form the side walls.

In the embodiment illustrated in FIG. 1, the common or “like” magnetic pole (i.e., the north pole) of each magnet of the magnetic cylindrical walls 102 and 104 each point radially towards the interior cavity 124 of the partial toroidal cylinder 100. Similarly, each magnet in the side walls 170 and 172 would also have their north poles facing the interior cavity 124.

Thus, the magnets forming the side walls 170 and 172 also produce flux forces represented by flux lines. The flux line from the magnets of the side walls 170 and 172 tends to flow from the north pole interior facing pole of the magnetic in a perpendicular manner, into the interior cavity 124 of the partial cylinder 100, through the iron core 110, out either the open end 114 or the open end 116 and into the open space 115, then back around the relevant side wall to south pole on the face of the originating magnet of the side wall. Thus, the side wall magnets also contribute to the flux field 125 (FIG. 1) generated by the magnets forming the cylinder walls 102 and 104.

FIG. 2b is a detailed partial view of the partial toroidal magnetic cylinder 100 illustrating the planar magnetic fields or “flux walls” 122 generated within the interior cavity 124 of the partial magnetic cylinder 100 in conjunction with the iron core 110. These are representative illustrations; the actual flux walls 122 or flux fields are dependent on the material design and configuration.

The partial magnetic cylinder 100 as presented in FIGS. 1, 2a and 2b have been conceptualized to illustrate the basic flux lines or paths of a partial magnetic cylinder with an iron core concentrically located in a hollow portion of its walls. From a practical perspective, a core or rotor assembly may position the core 110 within the magnetic cylinder 100. In yet other embodiments, the partial magnetic cylinder 100 may be a rotor rotating around a fixed stator.

FIGS. 3a through 3f illustrate an embodiment where a partial toroidal magnetic cylinder is configured as a rotor 300 in an electric motor or generator (not shown). FIG. 3a is a perspective view of two partial toroidal magnetic cylinders, each generating magnetic fields of opposite polarities. FIG. 3b illustrates the two partial toroidal magnetic cylinders joined together to act as the rotor 300. FIG. 3c is an exploded isometric view illustrating two halves or magnetic assemblies 301 and 303 which form the rotor 300. FIG. 3d is an isometric view of magnetic assembly 303 from an opposing angle showing details of the assembly which are not visible in FIG. 3c. FIG. 3e is section view of the rotor 300 which is transverse to the longitudinal axis 320 and illustrates details of the magnetic assembly 301. FIG. 3f is a

section view taken at and parallel to the longitudinal axis 320 showing the magnetic assemblies 301 and 303 coupled together to form the rotor 300.

FIG. 3a illustrates a partial toroidal magnetic cylinder 350 which is conceptually similar to the partial toroidal magnetic cylinder 100 discussed above in reference to FIGS. 1, 2a and 2b. As illustrated, there is an outer magnetic wall 302 and an inner magnetic wall 304. In addition to the partial cylindrical magnetic walls 302 and 304, there may also be magnetic side walls 370 and 372 which in this illustrated embodiment may be made of a plurality of wedge shape members or magnets. A section cut radially through the outer magnetic wall 302, the inner magnetic wall 304, and the magnetic side walls 370 and 372 would reveal a section of the four walls similar to the end 314 illustrated in FIG. 3A. The center of that section is known as the “sectional center.” The individual magnets in the magnetic walls all have their common or “like” magnetic poles (e.g. north poles) pointing towards an interior 324 of the partial toroidal magnetic cylinder 350. Although the shapes and number of the individual magnets of the partial toroidal magnetic cylinder 350 are different than the shape and number of individual magnets of the partial toroidal magnetic cylinder 100, the flux lines and magnetic fields are conceptually similar. In other words, the flux lines generated from an individual magnet of the partial toroidal magnetic cylinder 350 starts, for instance, at its north pole which is facing towards the interior 324 or “tunnel” of the partial toroidal magnetic cylinder 350. The flux lines then are channeled through the interior 324 of the partial toroidal magnetic cylinder 350 and flow out an open or terminating end, for instance, the end 314 into a throat or open area 315. The flux lines then follow around the exterior of the partial toroidal magnetic cylinder 350 and back to the south pole of the individual magnet. Such flux line action is described in detail with reference to the partial toroidal magnetic cylinder 100 described above. Thus, the partial toroidal magnetic cylinder 350 generates a flux field which is conceptually similar to the flux field 125 discussed above.

In some embodiments, when the partial toroidal magnetic cylinder 350 is designed to act as part of a rotor, it may be preferable to have a portion of the throat or the open area 315 filled with weights so to balance the mechanical rotation of the partial toroidal magnetic cylinder 350 when it turns about its center axis. In certain embodiments, a plurality of magnets may be used as balancing weights and/or to contribute to the overall power or current produced. If magnets are used in the throat 315, their polarities are reversed so as to not collapse the magnetic field created by the partial toroidal magnetic cylinder 350. In other words, two partial toroidal magnetic cylinders are used to form a single toroidal magnetic cylinder which may be used as a rotor or portion of a rotor.

A second partial toroidal magnetic cylinder 380 is designed to “fit” within the open area 315. The flux field generated by the second partial toroidal magnetic cylinder 380 is conceptually similar in shape to the flux field generated by the first partial toroidal magnetic cylinder 350 or 100 (discussed above in reference to FIG. 1). Specially, the flux lines from the magnets forming the second partial toroidal magnetic cylinder 380 run inward from the face of the magnets, then are channeled through the interior 384 or “tunnel” of the partial toroidal magnetic cylinder 380 and flow out an open or terminating end, for instance, the end 386. The flux lines then follow around the exterior of the partial toroidal magnetic cylinder 380 and back to the opposing pole of the individual magnet.

FIG. 3*b* illustrates a complete toroidal magnetic cylinder **390** formed from combining the two partial toroidal magnetic cylinders **350** and **380** where the partial toroidal magnetic cylinders each have opposite magnetic polarities and magnetic fields. The flux field formed by the partial toroidal magnetic cylinder **380** is said to have an opposite polarity from the flux field formed by the partial toroidal magnetic cylinder **350**. In other words, the magnets of the partial toroidal magnetic cylinder **380** are positioned such that their like poles are in an opposite direction from the magnets forming the partial toroidal magnet cylinder **350**. For instance, the like poles (e.g., the north poles) of the magnets forming the partial toroidal magnetic cylinder **350** all face inward towards the tunnel **324**. In contrast, the like poles (e.g., the north poles) of the magnets forming the partial toroidal magnetic cylinder **380** all face outward away from the tunnel **384**. Obviously, with regard to the partial toroidal magnetic cylinder **350**, it does not matter whether the north poles of the magnets face inward or the south poles face inward as long as the magnets forming the partial toroidal magnetic cylinder **380** have their respective like poles reversed.

In certain embodiments, the toroidal magnetic cylinder **390** may be assembled in longitudinal portions or halves: such as a first longitudinal portion **392** and a second longitudinal portion **394**. For instance, the longitudinal portion **392** may be incorporated into first a magnetic assembly **301** (FIG. 3*c*) and the longitudinal portion **394** may be incorporated into a second magnetic assembly **303** (FIG. 3*c*).

When the magnetic assemblies **301** and **303** are coupled together as illustrated in FIG. 3*f*, they create two outer magnetic cylinder walls **302a** and **302b** and inner magnetic cylinder wall **304**. When the magnetic assemblies **301** and **303** are coupled together, the outer magnetic cylinder walls **302a** and **302b** are conceptually similar to the outer cylinder wall **102** discussed above, except there is a slot **305** defined between to allow a portion of a stator (not shown) to pass through. Similarly, the inner magnetic cylinder wall **304** is conceptually similar to the inner cylinder wall **104** discussed above. As illustrated in FIGS. 3*c* and 3*d*, it can be seen that the outer magnetic cylinder walls **302a** and **302b** are comprised of a plurality of individual magnets **306**. Similarly, the inner magnetic cylinder wall **304** may be comprised of a plurality of individual magnets **308**.

As with the partial toroidal magnetic cylinder **100** discussed above, only one polarity of the magnets in the plurality of magnets **306** and **308** are utilized within (or facing into) an interior cavity **324** of the toroidal magnetic cylinder or rotor **300** forming a region of magnetic concentration. For instance in the illustrative embodiment of FIG. 3*d*, the north poles of the plurality of magnets **306** are each pointing radially towards a longitudinal axis **320** of a longitudinal shaft **352**. On the other hand, the north poles of the plurality of magnets **308** each point radially away from the longitudinal axis **320** and towards the interior cavity **324** of the magnetic assembly **303** (or the rotor **300** when assembled).

In addition to the partial cylindrical magnetic walls **302** and **304**, there may also be magnetic side walls **370** and **372** which in this illustrated embodiment may be made of a plurality of wedge shape members. When the magnetic assemblies **301** and **303** are coupled together, the side walls **370** and **372** join the exterior cylindrical wall **302** to the interior cylindrical wall **304**. In certain embodiments, the side walls **370** and **372** may be made of a plurality of side wall magnets **374**. When the side wall members are a plurality of side wall magnets **374**, the magnets have their

common poles facing the interior of the toroidal center **324**. For instance, if the common pole (e.g., north pole) of the plurality of magnets **306** and **308** point towards the toroidal interior cavity **324**, the north pole of the magnets **374** would also have their north poles pointing towards the toroidal center cavity **324**. Thus, the plurality of magnets **374** would also contribute to the cumulative magnetic flux field produced by the inner and outer partial toroidal magnetic cylinders **302** and **304** as explained above and explained in detail with reference to FIG. 1.

A second group of magnets positioned within the “throat” form a portion of the second partial toroidal cylinder **380**. For sake of illustration, such magnets are labeled in FIG. 3*d* with an “S” representing a facing “South” pole—as opposed to the magnets labeled with an “N” representing a facing “North” pole.

In certain embodiments, there may be a first outer support **360** to position and structurally support the plurality of magnets **304**, **306**, and **374** comprising a portion of the magnetic assembly **301**. There may also be a second outer support **362** to position and structurally support the plurality of magnets **304**, **306**, and **374** that are a part of the magnetic assembly **303**. In certain embodiments, the outer support **360** may be formed by a cylindrical wall **364a** (FIG. 3*c*) and a side wall **366a** (FIG. 3*f*). Similarly, the outer support **362** may be formed a cylindrical wall **364b** and a side wall **366b** (FIGS. 3*c* and 3*f*). The outer supports **360** and **362** may be formed from either non-conductive materials or conductive materials, such as steel, iron, or aluminum, depending on the design requirements and ultimate application of the motor.

In the embodiment illustrated in FIGS. 3*a* through 3*f*, there may also be an inner support or hub **368** (see FIG. 3*d*), which positions and structurally supports the inner magnetic cylinder **304**. In certain embodiments, the hub **368** may be coupled to one of the outer supports, such as the outer support **362**. The hub **368** may also be coupled to a longitudinal shaft **352** by conventional means known in the art (see FIG. 3*d*).

In certain embodiments, the longitudinal shaft **352** may be made from an iron, steel or similar alloy. The hub **368** may be made from iron, steel or similar alloy, or a ferrite compound. In some embodiments, the ferrite compound or powder may be suspended in a viscous material, such as an insulating fluid, a lubricant, motor oil, a gel, or mineral oil.

As discussed above, the magnets of the plurality of magnets **306**, **308** and **374** may be made of out any suitable magnetic material, such as: neodymium, Alnico alloys, ceramic permanent magnets, or electromagnets. The exact number of magnets or electromagnets will be dependent on the required magnetic field strength or mechanical configuration.

FIG. 3*e* is an interior view of the magnetic assembly **301** taken perpendicular to the longitudinal axis **320**. At the outer periphery, the cylindrical wall **364a** of first outer support **360** is shown encapsulating the magnetic assembly **301**. In proximity to the cylindrical wall **364a**, there is outer magnetic cylinder wall **302a** comprising the plurality of magnets **306**. In the illustrative embodiment, there are approximately sixteen (16) magnets in the plurality of magnets **306**. As illustrated by the arrows **310**, each of the magnets in the plurality of magnets **306** has its north pole facing inwards towards the longitudinal axis **320**. Similarly, at the inner face of the partial cylinder, there is the inner magnetic wall **304**. In this illustrative embodiment, the inner magnetic wall **304** comprises the plurality **308** of seven (7) magnets where each of the seven magnets has its north pole facing away from the longitudinal axis **320** as represented by the arrows **312**. Also

11

illustrated is the magnetic side wall **366a** comprising the plurality of magnets **374** which include twelve (12) side wall magnets having their north poles facing away from the paper or towards the interior cavity **324** (when assembled into one rotor **300** as illustrated in FIG. **3b**).

Thus, when the common pole (i.e., north pole) magnets comprising the plurality of magnets **306**, **308**, and **374** are viewed as illustrated in FIG. **3e**, it is apparent that they form a first portion or one half **392** of a partial toroidal magnetic cylinder **350** (FIG. **3b**), similar to the partial toroidal magnetic cylinder **100** discussed in reference to FIG. **1**. When combined with the opposing portion or half **394** of magnetic assembly **303** (not shown in FIG. **3e**), it is apparent that the flux lines and the resulting magnetic field **325** (not shown for clarity) will be conceptually similar to the flux lines **112** and the magnetic field **125** discussed above in reference to FIG. **1**.

As illustrated in FIG. **3e**, the throat area **315** is generally within the area defined by an angle β taken about the longitudinal axis **320**. In the illustrative embodiment, the magnets within this area or throat include two magnets **328a** and **328b** which form a portion of an interior cylindrical wall, four magnets **330** which form a portion of a side wall, and four magnets **332** which form a portion of an exterior cylindrical wall. In contrast to the plurality of magnets **306**, **308**, and **374**, comprising the partial toroidal magnetic cylindrical where there "common" (e.g., north poles) all face inward towards the interior cavity **324**, the magnets **328**, **330**, and **332** have their "common" (e.g., south poles) all facing inwards towards the interior cavity **324**.

Thus, as discussed above, the magnets **328**, **330**, and **332** may form the second partial magnetic toroidal cylinder **380** where the magnets in the magnetic toroidal cylinder **380** are positioned such that their like poles are opposite to the like poles of the magnets forming the first partial magnetic toroidal cylinder **350** (see FIG. **3a**). When fully assembled, the first partial magnetic toroidal cylinder **350** and the second partial magnetic toroidal cylinder **380** form the complete toroidal cylinder **390** (FIG. **3b**) having two distinct magnetic fields. Unlike typical electric motors and generators, the angle β can be anywhere from 180 degrees to as little as approximately 25 degrees. However, if either of the partial toroidal magnetic cylinders **350** or **380** were to be completely filled with magnets of like poles to those making the cylinders, the external magnetic field **325** (or the magnetic field **125** discussed in reference to FIG. **1**) would collapse rendering the field practically useless for energy conversion.

Similar to the embodiment discussed in reference to in FIG. **1**, the partial toroidal magnetic cylinder **350** thus has two magnetic ends **314** and **316** that are functionally equivalent to the open throat as shown in FIG. **1** with ends **314** and **316** forming the throat **315** between the two magnetic ends.

Turning now to FIG. **4a**, there is one illustration of a coil assembly functioning as a stator **400** which may be used in conjunction with the rotor **300** of FIGS. **3a** through **3d**. In FIG. **4a**, there is illustrated an isometric view of the stator **400**. FIG. **4b** illustrates an isometric view of a similar, but alternative embodiment of a stator **400'**. FIG. **4c** illustrates a section view of the stator **400** or the stator **400'**. FIG. **4d** illustrates a conceptual wiring diagram for one embodiment of the stator **400**.

As can be seen from FIGS. **4a** and **4c**, the stator **400** or the stator **400'** comprises a cylindrical or ring core, such as an iron core **402**, a connecting ring support assembly **404** and a plurality of coils or windings **406** (or, alternatively, at least one coil or winding). The iron core **402** is conceptually

12

similar to the core **110** discussed above in reference to FIG. **1**. The iron core **402** is coupled to the plurality of coils **406** using conventional fastening methods known in the art. (In other embodiments, the iron core **402** may consist of two or more segments which may be fastened together to form a complete ring or core. These embodiments may have the benefit of allowing the plurality of coils **406** to be built on conventional forms then added to the ring segments.) Although an iron core is used in this embodiment as a magnetic flux line concentrator, other core materials may be used when design considerations such as mechanical strength, reduction of eddy currents, cooling channels, etc. are considered. In fact, certain embodiments may not use the central iron core **402**.

In the embodiment illustrated in FIGS. **4a** to **4c**, the plurality of coils **406** are positioned radially about the core **402** to form a coil assembly **408**. Each individual coil **406a** in the coil assembly **408** may be made from a conductive material, such as copper (or a similar alloy) wire and may be constructed using conventional winding techniques known in the art. In certain embodiments, the individual coils **406a** may be essentially cylindrical or rectangular in shape being wound around a coil core (not shown) having a center opening sized to allow the individual coil **406a** to be secured to the core **402**. The windings of each coil **406a** are generally configured such that they remain transverse or perpendicular to the direction of the relative movement of the magnets comprising the rotor **300** and parallel with the longitudinal axis. In other words, the windings are positioned such that their sides are parallel with the longitudinal axis and their ends are radially perpendicular to the longitudinal axis. The windings are also transverse with respect to the magnetic flux produced by the individual magnets of the rotor at their interior face as described above. Consequently, the entire winding or windings may be used to generate movement (in motor mode) or voltage (in generator mode).

The number of coils **406** can be any number that will physically fit within the desired volume and of a conductor length and size that produces the desired electrical or mechanical output as known in the art. In certain embodiments, the coils **406** may be essentially one continuous coil, similar to a Gramme Ring as is known in the art.

In embodiments using the coil assembly as a stator, the circumferential or transverse slot formed within the exterior cylinder wall **102** (FIG. **1**) may allow the flux formed within the tunnel to leak out of the tunnel. This "leakage flux" through the transverse slot may be redirected back into the tunnel by coupling a series or plurality of radial magnets **403** to the connecting ring support **404** close to where the connecting ring intersects the transverse slot (not shown). The plurality of magnets **403** may be oriented similar to the cylinder magnets **106** of the cylinder **100** (not shown in FIG. **3**). In other words, the plurality of magnets **403** may be oriented such that their common poles (i.e., north pole) face the interior cavity **124** of the tunnel. In other embodiments, the plurality of magnets **403** are orientated so they just establish a transverse flux field to redirect the leakage flux back into the tunnel. In certain embodiments, the plurality of magnets **403** may be placed on each side of the connecting ring support **404** as illustrated in FIG. **4b**. In yet other embodiments, the plurality of magnets may be placed within the connecting ring support **404**.

FIG. **4c** is a conceptual exemplary wiring diagram of the stator **400**. A power rail **410** is represented by an outer circle or wire **412** representing a positive supply and an inner circle or wire **414** representing a negative supply. In this embodiment, the coils **406** are connected in series with each other

13

and the leads from each coil **406** are brought out to a junction point **416** which is then connected to a positive switch **418** which, in turn, is connected to the positive supply **412** of the power rail **410**. The junction point **416** is also connected to a negative switch **420** which is connected to the negative supply **414** of the power rail **410**. Each positive switch **418** connects to a positive injection point **422** and each negative switch **420** connects to the negative power injection point **424** of the power rail **410**.

FIG. **4e** and FIG. **4f** illustrate an alternative embodiment of a coil assembly functioning as a rotor **450**. Turning now to FIG. **4e**, there is presented an isometric view of a one embodiment of an assembly **450** comprising an iron core **452**, a rotor hub **454** and shaft **456**. The iron core **452** is conceptually similar to the core **110** discussed above. The iron core **452** and the rotor hub **454** are fastened to a shaft **456** using conventional fastening methods known in the art. In certain embodiments the rotor hub **454** may be composed of non-ferrous materials to eliminate the production of eddy currents. When assembled with the partial magnetic cylinder **100**, a transverse slot or circumferential (not shown) in the inner wall **104** of the partial magnetic cylinder (not shown in FIG. **4e**) allows a portion of the rotor hub **454** to extend through the inner wall **104** of the partial magnetic cylinder **100** and into the interior cavity **124** to position the core **452** within the interior cavity of the partial magnetic cylinder (See FIG. **2b**).

In other embodiments, the iron core **452** may consist of two or more segments **460a** and **460b** which may be fastened together to form a complete ring or core. This configuration may have the benefit of allowing a plurality of coils to be built on conventional forms then added to ring segments.

FIG. **4e** illustrates an isometric view of the rotor assembly **450** where the core **452** comprises the core segment **460a** and the core segment **460b**. A single coil **462a** is illustrated and positioned about the core segment **460b**. In certain embodiments, there may be a plurality of coils **462** rotationally positioned about the core **452** as described above when the coil assembly acts as a stator. Each individual coil **462a** may be made from a conductive material, such as copper (or a similar alloy) wire and may be constructed using conventional winding techniques known in the art. In certain embodiments, the individual coils **462a** may be essentially cylindrical in shape being wound around a coil core (not shown) having a center opening sized to allow the individual coil **462a** to be secured to the core **452**.

In embodiments using the coil assembly as a rotor, the circumferential or transverse slot formed within the interior cylinder wall **104** (FIG. **1**) may allow the flux formed within the tunnel to leak out of the tunnel. This "leakage flux" through the transverse slot may be redirected back into the tunnel by coupling a series or plurality of radial magnets **458** to the rotor hub **454** close to where the rotor hub intersects the transverse slot. The plurality of magnets **458** may be oriented similar to the cylinder magnets **106** of the cylinder **100** (not shown in FIG. **3**). In other words, the plurality of magnets **458** may be oriented such that their common poles (i.e., north pole) face the interior cavity **124** of the tunnel. In certain embodiments, the plurality of magnets **138** will move with the rotor assembly **450**. In yet other embodiments, the plurality of magnets are orientated so they just establish a transverse flux field to redirect the leakage flux back into the tunnel. In certain embodiments, the plurality of magnets may be placed on each side of the hub **454**. In yet other embodiments, the plurality of magnets may be placed within the hub **454**.

14

FIG. **5a** is a cross-sectional view of one embodiment of an electric motor/generator assembly **500** illustrating the stator **400** positioned within the first magnetic assembly **301** and the second magnetic assembly **303** of the rotor **300**. FIG. **5b** is a transverse cross-section of one embodiment of an electric motor/generator assembly **500** illustrating the coil assembly **408** of the stator **400** positioned within the magnetic assembly **301** of the rotor **300**. FIG. **5c** is a transverse cross-section of one embodiment of an electric motor/generator assembly **500** illustrating the switch configuration of the coil assembly **408** when the magnetic assembly **301** of the rotor **300** is in a first rotational position. FIG. **5d** is a transverse cross-section of one embodiment of an electric motor/generator assembly **500** illustrating the switch configuration of the coil assembly **408** when the magnetic assembly **301** of the rotor **300** is in a second rotational position. FIG. **5e** is a transverse cross-section of one embodiment of an electric motor/generator assembly **500** illustrating the switch configuration of the coil assembly **408** when the magnetic assembly **301** of the rotor **300** is in a third rotational position.

FIG. **6a** is a cross section view of the assembly **500** positioned within an assembled motor **600**. FIG. **6b** is an exploded perspective view of the motor **600**. In certain embodiments, there may be an outer casing or housing **602** (or alternatively, two portions of the housing, e.g. housing portion **602a** and housing portion **602b**) which provides structural support for the rotor **300** and stator **400**, and the longitudinal shaft **352**. In certain embodiments, the housing **602** may be formed from any material, alloy, or compound having the required structural strength and may be actually made from two housing components. In certain embodiments, non-ferrous materials may be used as there is essentially no detectable external magnetic field from the rotor. In some embodiments, external bearings **606** may be used to reduce the friction between the longitudinal shaft **352** and the housing **602** or a similar supporting structure. In certain embodiments, the housing **602** may be coupled to a base **604** to provide for structural support for the housing **602**. As is well known, in the art, the motor **600** may also be coupled to a controller appropriate for the desired output from the machine (not shown).

Operation—Motor Mode:

Turning back to FIG. **4c**, electric power is applied to the power terminals (not shown) which energizes the power rail **410** (see FIG. **4c**). Current begins to flow in the individual coils in the plurality of coils **406** that are electrically connected to the power rail **410** and sequentially controlled via the plurality of positive switches **418** and negative switches **420**. As is well known in the art, when current flows through certain coils **406** a magnetic field is created. When certain coils **406** are within the magnetic field **325** created by the partial toroidal magnetic cylinder **350**, the partial toroidal magnetic cylinder **350** and the rotor **300** begins to move relative to the energized coils because of the electromotive forces asserted on the partial toroidal magnetic cylinder **350**.

As the rotor **300** and the partial magnetic field **325** rotates about the stator **400** comprising the coils **406**, certain coils of the plurality of coils **406** will always be out of the partial toroidal magnetic cylinder **350** portion of the rotor and will be within the throat **315**. By adding a second partial toroidal magnetic cylinder **380**, it is possible for the coils outside of the partial toroidal magnetic cylinder **350** (i.e., the coils within the throat **315**) to also contribute to the overall rotation force or torque on the shaft **352**. As the throat **315** moves with respect to the coils, flux is now leaving the

15

interior cavity **324** on its path to the external walls of the partial magnetic cylinder which is in the opposite direction to the flux forces within the partial magnetic cylinder, thus each coil in the throat **315** may be supplied with a reverse polarity via the plurality of switches **416** to contribute torque.

Turning to FIG. **5b** which illustrates a section view of the assembled motor **600**. FIG. **5b** shows a coil **406a** which is now within the interior cavity **325** of the partial toroidal magnetic cylinder **350** and a coil **406b** which is within the throat **315** (defined by the angular area created by the angle **R**). From the perspective of a coil, each coil injection point is energized at the proper time so that the coil remains energized only while the coil is within the interior cavity **325** of the partial toroidal magnetic cylinder **350** (e.g. coil **406a**) and not energized (or energized with a negative current flow) when the coil (e.g. coil **406b**) is within the throat **315**.

Voltage is injected via the power terminals of the motor **600** (not shown), thereby causing current to flow along the power rail **410**. A positional sensor (not shown), for instance, at the open end **314** of the partial toroidal magnetic cylinder **350** signals a controller (not shown) which in turn activates the appropriate positive switch **418** and the negative switch **420** so that the coils receive a current flow of correct polarity as the coil enters the throat **315** (see FIG. **4c**). Thus, a portion of the current from the power rail **410** may travel clockwise from the negative power of the rail through the switch to a coil to the next coil, etc. for the coils that are within the interior cavity **324**. The remainder of the current travels counterclockwise from the switch, to a coil to the next coil, etc. for the coils that are within the throat **315**.

By way of example, FIG. **5c** illustrates a first exemplary position of eight coils (similar to the coils **406** of FIG. **5b**) and an exemplary wiring diagram. As illustrated, at the first exemplary position, the 70 degree angle throat **315** is pointed downwards such that coil **8** and coil **1** are in the throat **315**. In contrast, the coils **2** through **7** are within the interior cavity or tunnel of the partial toroidal magnetic cylinder **350**. A positional sensor alerts a controller as to the position of the toroidal magnetic cylinder **350**, which in turn, opens or closes the appropriate switch **418** or **420**. For instance, once the appropriate switches are configured, negative current is received at an injection point **424a** along the negative rail **414**. The current flows through the switch **420a** into the junction **416a** which splits the current into essentially two circuits in a parallel configuration. The first circuit comprises the coils **1** and **8**. The second circuit comprises coils **2** through **7**. The current flows between the two circuits in accordance with the relative resistance of both circuits. Thus, a portion of the circuit flows clockwise through coil **1** and coil **8** to the junction **416d**, through the positive switch **418a** and onto the positive rail **412** of the power rail **410**. Similarly, a portion of the current flows counterclockwise through coils **2** through **7** to the junction **416d**, through the positive switch **418a** and onto the positive rail **412** of the power rail **410** via injection point **422a**.

FIG. **5d** illustrates a second exemplary position of eight coils and an exemplary wiring diagram. As illustrated, at position two, the 70 degree angle throat **315** has been rotated slightly in a counterclockwise direction such that only coil **1** is in the throat. In contrast, the coils **2** through **8** are within the interior cavity or tunnel of the partial toroidal magnetic cylinder **350**. A positional sensor alerts a controller as to the position of the toroidal magnetic cylinder **350**, which in turn, opens or closes the appropriate switch **418** or **420**. For instance, once the appropriate switches are configured, negative current is received at an injection point **424b** along the

16

negative rail **414**. The negative current flows through the switch **420b** into the junction **416b** which splits the current into essentially two circuits in a parallel configuration. The first circuit comprises the coil **1**. The second circuit comprises coils **2** through **8**. The current flows between the two circuits in accordance with the relative resistance of both circuits. Thus, a portion of the current flows clockwise through coil **1** to the junction **416e**, through the positive switch **418b** and onto the positive rail **412** of the power rail **410**. Similarly, a portion of the current flows counterclockwise through coils **2** through **8** to the junction **416e**, through the positive switch **418b** and onto the positive rail **412** of the power rail **410** via injection point **422b**.

FIG. **5e** illustrates a third exemplary position of eight coils and an exemplary wiring diagram. As illustrated, at position three, the 70 degree angle throat **315** has been rotated slightly in a counterclockwise direction such that coil **1** and coil **2** are in the throat. In contrast, the coils **3** through **8** are within the interior cavity or tunnel of the partial toroidal magnetic cylinder **350**. A positional sensor alerts a controller as to the position of the toroidal magnetic cylinder **350**, which in turn, opens or closes the appropriate switch **418c** or **420c**. For instance, once the appropriate switches are configured, negative current is received at a negative injection point **424c** along the negative rail **414**. The negative current flows through the negative switch **420c** into the junction **416c** which splits the current into essentially two circuits in a parallel configuration. The first circuit comprises the coils **1** and **2**. The second circuit comprises coils **3** through **8**. The current flows between the two circuits in accordance with the relative resistance of both circuits. Thus, a portion of the current flows clockwise through coils **1** and **2** to the junction **416f**, through the positive switch **418c** and onto the positive rail **412** of the power rail **410**. Similarly, a portion of the current flows counterclockwise through coils **3** through **8** to the junction **416f**, through the positive switch **418c** and onto the positive rail **412** of the power rail **410** via injection point **422c**.

This cycle of switching and forming two new parallel circuits repeats as the rotor rotates around the stator and new coils are included in the throat as described above.

Reversal of rotor rotation is a logic sequence of switch activation in reverse of previously stated switching sequences, as opposed to a brushed unit where reversal is best accomplished by reverse polarity at the power injection brushes.

For instance turning back to FIG. **5b**, the coil **406b** is now positioned in the throat **315** as the partial toroidal cylinder **350** rotates around the longitudinal shaft **352**. The partial toroidal cylinder **350** will soon rotate such that the coil **406b** will be in the interior cavity **324** as the open end **314** of the partial toroidal cylinder **350** engulfs the coil. Likewise, a portion of the established static magnetic field **325** is rotating so that it will engulf the coil **406b**. As described above, the coil **406b** receives a current within the windings of the coil from the power rail **410**. As the current flows in the windings, a magnetic field is formed around the windings. This magnetic field of the coil **406b** interacts with the first portion of the magnetic field **325** as the coil is engulfed by the open end **314** which causes an electromotive force on the partial toroidal cylinder **350** and the rotor **300**. In turn, the electro-motive force on the partial toroidal cylinder **350** transfers to the rotor hub **368**. The rotation force on the rotor hub **368** is then applied to the longitudinal shaft **352**—causing the shaft to rotate.

As the partial toroidal magnetic cylinder **350** continues to rotate, the interior cavity **324** and the flux field therein

continues to surround and pass the coil **406b**. When the partial toroidal cylinder **350** rotates completely around the coil **406b** such that the open end **316** passes the coil, the current at the coil is then reversed by the appropriate sensor and switches. This current reversal causes a continuation of the previous movement and direction of the partial toroidal cylinder **350** with respect to the coil **406b** and continues while the coil **406b** is now within the throat **315**. This rotational cycle then repeats as the partial toroidal cylinder **350** continues to rotate about the longitudinal axis **320**.

Operation—Generator Mode:

In the generator mode, when the partial toroidal cylinder **350** engulfs a portion of the plurality of coils **406** as the partial toroidal cylinder **350** rotates as the shaft **352** is being rotated, the coils within the partial toroidal magnetic cylinder only see the “flux walls” (as discussed in reference to FIG. **2b**). They may not be affected by the direction of flux within the core, thus the coils produce power while the partial toroidal magnetic cylinder **350** travels around them. However during the period of time the coils are in the throat **315**, it is possible that the coils can also contribute to the power being produced. During this transition period when the coils **406** are in the throat **315**, the flux is now leaving the iron core **332** on its path to the external walls **302**, **304**, **370** and **372** of the partial toroidal magnetic cylinder **350** which is, however in the opposite direction to the flux forces within the partial toroidal magnetic cylinder. Thus, the coil **406** can also produce usable power even in the throat **315** which can be utilized depending on design needs.

As discussed above, the shaft **352** receives a rotational force from an external rotational force inducing mechanism known in the art (not shown). In response to this rotational force, the shaft begins to rotate. As the rotor hub **368** is coupled to the shaft **352**, the rotor hub also begins to rotate which in turn rotates the rotor **300**. As discussed above, the rotor **300** is coupled to the partial toroidal magnetic cylinder **350** radially positioned around a portion of its periphery and a throat **315** positioned around the remaining portion of its periphery. From the perspective of coils, the coil **406b** is within the throat until the partial toroidal magnetic cylinder **350** rotates around and engulfs the coil.

As the open end **114** begins to engulf the coil **406b**, the first portion of magnetic field **325** having concentrated magnetic flux as discussed above also surrounds the coil. The rotational movement of the magnetic field **325** with respect to the coil **406a** within the concentrated flux field **325** induces a voltage to appear in the terminal ends of the coil. This voltage generated is added to the voltage generated by the remainder of the coils. The voltage causes current to flow through the switches and on to the power rail **410**. As the magnetic cylinder throat rotates the appropriate switches are sequentially operated to allow current to flow to the power rail. The power rail **410** is coupled to an external closed circuit (not shown) via the power terminals (not shown).

The continuous movement of the concentrated flux field **325** with respect to the coil **406b** continues to induce a voltage to appear in the terminal ends of the coil as the concentrated flux field moves around the coil. The continuous voltage causes a continuous current to flow through the switches and then to the power rail **410** which is electrically coupled to an external closed circuit via the power terminals (not shown).

The continued movement of the partial toroidal magnetic cylinder **350** causes the open end **314** (and the magnetic field **325**) to rotate past the coil **406b**. Thus, the coil **406b** is now within the throat **315**. The movement of the throat **315**

engulfing the coil **406** causes a voltage of an opposite polarity to be induced into the coil **406b** and appears in the terminal ends of the coil causing current in the windings of the coil to flow in a reverse direction.

The continuous movement of the throat **315** past the coil **406b** within the second portion of the concentrated flux field continues to induce a voltage to appear in the terminal ends of the coil. The continuous voltage causing continuous current to flow while the coil is in the throat **315** which in turn flows through the switches **416** to the power rail **410** which is coupled to an external closed circuit via the power terminals.

However, the output voltage from the power rail **410** does not change polarity at any point due to the effect of the positional sensor, controller, and switches **416**. Thus, the output is DC.

This rotational cycle then repeats as the partial toroidal magnetic cylinder **350** continues to rotate about the longitudinal axis **320**.

FIG. **7a** is a communication flow diagram of various exemplary control components of the motor/generator. For example, a voltage/current controller **704** may receive power from an electric power source **702**. The voltage/current controller **704** may limit and control the power sent on to motor power rail supply **706** (e.g., the power rail **410** of FIG. **4**). A throat position logic and power injection point switching module **708** uses sensor feedback to control which switches are closed in the motor **710** as discussed in reference to FIGS. **5c** through **5d** above. In certain embodiments when speed or torque control is required, a “revolutions per minute” or RPM encoder **712** tracks the speed of the rotation and sends RPM indication signals back to the voltage/current controller **704**, which in turn adjusts the power sent to the power rail to either increase or decrease the RPM depending on the parameters programmed or set in the voltage/current controller **704**.

FIG. **7b** is a circuit diagram of one embodiment of an exemplary sensor and switching control circuit **750** such as the sensor and switching control circuit **708** of FIG. **7a**. In this embodiment, there is a controller or throat position sensor logic board **752** which receives signals from a plurality of sensors **754** (labeled as sensors **1** through **5** in FIG. **7b**). The plurality of sensors **754** are positioned about individual coils of a plurality of coils **756** making up a coil assembly, for instance the coil assembly **408** (See FIG. **4a**). The plurality of sensors **754** determine the rotational position of the rotor or rotor assembly with respect to the stator (and the plurality of coils **756**). In this exemplary embodiment, the switching sequence merely follows the movement of the rotor and does not control torque or speed. As discussed above, each coil in the plurality of coils **756** is also connected to a plurality of junction points **758** (i.e., junction points **416** of FIG. **4c**). The junction points **758** are connected to a plurality of positive and negative switches **780** (i.e., positive switches **418** and negative switches **420** of FIG. **4c**). In this embodiment, the plurality of positive and negative switches may be a plurality of MOSFET transistors **760**.

Referring also to FIGS. **5c** through **5e**, the control circuit **750** may be activated in the following sequence: As the throat **315** moves to surround Coil **1**, position sensor **1** is activated, a signal is sent to the Throat Position Sensor Logic Board **752**. A MOSFET gate driver is then activated to close the appropriate positive MOSFET for the sensor **1** coil **1** position and to the appropriate negative MOSFET coil **1** and coil **2** negative junction. In FIG. **5c**, this action would then allow current to travel to Coil **1** via a positive Mosfet and

Coil 1 via coil 2 Negative Mosfet. Correspondingly, current will also flow through coils 2 through 7 via the positive Mosfet (e.g., Junction 416a) and a Negative Mosfet (e.g., Junction 416d). Sensor 1 will stay activated during the duration coil 1 is in the throat. As the throat moves to surround Coil 2, sensor 2 is activated. This Input from sensor 2 and the input from active sensor 1 deactivates Coil 1-coil 2 Negative Mosfet and sends a signal to the gate on Coil 2 and coil 3 negative Mosfet. Both Coils 1 and 2 now have current of the same polarity flowing through them (FIG. 5e). As the throat moves to surround Coil 3 sensor 1 is no longer active which deactivates Coil 1 positive mosfet. And sensor 3 now activates Coil 1 and coil 2 junction Positive Mosfet. This action would allow current to travel to Coil 2 positive Mosfet and Coil 2-coil 3 Negative Mosfet. Correspondingly, current will also flow through coils 3 through 8 via a positive Mosfet (e.g., Junction 416f) and a Negative Mosfet (e.g., Junction 416c). The sequence then repeats as the rotor moves from sensor to sensor.

FIG. 8a illustrates conceptual flux lines 916 of a hybrid magnet assembly 900. Conceptually similar embodiments to the hybrid magnet assembly 900 might be used with various embodiments disclosed above. One skilled in the art may see that though some of the aligned magnetic domains will contribute to flux lines 916 exiting the permanent magnets pole faces, however, most will "leak" out of the core side walls 918.

FIG. 8b illustrates the hybrid magnet assembly 900 with a spirally wrapped a conductive material 920 carrying a current. Conceptually similar hybrid magnet assemblies with conductive material may be used with the various disclosed embodiments above to overcome the disadvantages of using the hybrid magnet assembly 900. As illustrated, the conductor 920 confines and concentrates the flux lines 916 to align any magnetic domains not aligned by the permanent magnets. This addition allows the creation of much stronger magnetic flux outputs at a lower ampere turn levels than conventional iron core coils.

Thus, such "hybrid" magnet assemblies can also be used to assist in the concentration of flux force lines in the partial magnetic cylinders discussed above.

Advantages of Certain Embodiments

Disclosed above are methods and systems of increasing flux density utilizing commercially available shapes or sizes that can be chosen based on lower cost rather than flux density. Also described are methods of producing mechanical power by moving a coil/s coupled to a core into a magnet assembly with an increased flux density or producing an electrical output power when the coils are mechanically forced through the magnetic assembly with an increased flux density. In certain aspects, within the magnetic cylinder or magnet assembly magnetic flux lines are created and increased by the configuration of permanent magnets or electromagnets and are restrained within the magnetic cylinder or magnet assembly until exiting at predetermined locations.

In certain aspects presented herein, non-pulsating or non-sinusoidal DC current is applied to the power terminals which produces a Lorentz force at each length of coil conductor. This force is applied continuously throughout the entire rotation of the rotor hub without variations in amplitude or interruptions in output power. There are no pole pieces to provide magnetic attraction or repulsion consequently, there is reduced torque ripple, polarity reversals or

interruptions in power output while the poles are in the process of reversing, thus producing more efficient output than traditional motors

When certain aspects of the disclosed embodiments are used as a generator non pulsating or non-sinusoidal DC current is produced at the power terminals. A Lorentz force at each length of coil conductor and across all coils induces an output current flow. This output is supplied continuously throughout the entire rotation of the rotor hub without variations in amplitude, polarity reversals, or interruptions in output power. There are no pole pieces to provide magnetic attraction or repulsion which produces a current output more efficiently than traditional generators.

Certain aspects of the disclosed embodiments reduce or eliminate the undesired effects and losses of traditional generators and motors discussed above, including Iron Hysteresis losses, Counter-EMF, inductive kickback, eddy currents, inrush currents, torque ripple, heat losses, cogging, brush losses, sparking and high wear in brushed designs, commutation losses and magnetic buffeting of permanent magnets.

In summary, certain aspects of the various disclosed embodiments may provide the following benefits:

Unlike conventional brush rectified or PWM controller motor/generators, the coils in aspects of this invention are in continuous contact with the Permanent Magnet field and thus produce a non-varying continuous torque or output.

Complex PWM drives and controllers, commutators, etc (and the associated losses) may not be not required since certain aspects of the invention produce and utilize DC current directly.

If automatic speed control for a given load is required, complex position indication is not required. A much simpler RPM indication and a varying voltage/current relationship is all that is required to control speed.

Using the magnetic cylinder/single pole magnet assembly concept utilizing permanent magnets an otherwise unachievable, extremely strong magnetic field is generated without consuming any electrical power.

Though a Counter EMF field is produced by any induced current flow, due to the magnet cylinder and core design there is no direct impact on coil movement that hinders such movement.

Iron Hysteresis losses are essentially eliminated as only two points on the core experience any hysteresis loss at all and then only twice per revolution.

Eddy current losses are essentially eliminated as the core does not move perpendicular to the flux lines

Cogging is also essentially eliminated as the core forces are balanced and equal in all directions

There is little inrush current as there is no need to saturate large masses of iron

Nearly 100% of the copper windings in the coil is utilized to take advantage of Lorentz forces thus there is no wasted copper winding as in conventional motor/generators.

Inductive kickback from the rising and collapsing sinusoidal waveform is eliminated

Like other DC motors reversal of torque is simply a reversal of input polarities.

Additionally, as every coil is continuously involved in output power, and with differing switching combinations other important benefits can be realized that are not possible with existing motor designs e.g. certain aspects of the various disclosed embodiments may provide the following benefits:

21

Coils may be recombined on the fly in varying series and parallel connections to enable changes in system current flow and thus output torque without changes in voltage,

Bypass faulted, shorted or open coils on the fly allowing emergency and continued operation of the motor or generator outputs,

Allow regenerative braking by utilizing one or more coils to be connected to an external load,

Apply active braking by utilizing one or more coils to apply an opposing force with application of power to select coils,

Allow fine control of shaft positioning by utilizing one or more coils to offset applied torque,

Reverse operation as a motor may be accomplished by reversing main power supply polarity or reversing logic switch sequence.

In other embodiments each coil's output is individually rectified before being sent to the power rails.

The invention claimed is:

1. A DC generator/motor, comprising:
 - a housing;
 - a rotor, comprising
 - a first partial toroidal magnetically closed cylinder including
 - a first partial cylindrical magnetic wall positioned about a longitudinal axis and having a first end and a first opposing end,
 - a first opposing partial cylindrical magnetic wall positioned at a predetermined radial distance from the first partial cylindrical magnetic wall, having a second end and a second opposing end and having a first circumferential slot defined therein,
 - a first side wall portion spanning from the first end to the second end,
 - a first opposing side wall portion positioned at a first longitudinal distance from the first magnetic side wall spanning from the first opposing end to the second opposing end,
 - wherein the first partial cylindrical magnetic wall, the first opposing partial magnetic cylindrical wall, the first side wall portion, and the first opposing side wall portion each have a surface and a corresponding magnetic pole of a first polarity that points towards a sectional center of the first partial toroidal magnetically closed cylinder that generate flux forces within the first partial toroidal magnetically closed cylinder;
 - a center shaft positioned along the longitudinal axis and coupled to the first partial toroidal magnetically closed cylinder;
 - a stator comprising
 - a support ring coupled to the housing and having a portion sized to fit within the first circumferential slot,
 - a plurality of coils coupled to the support ring and positioned radially about the longitudinal axis such that the plurality of coils and are sized to allow the first partial toroidal magnetically closed cylinder to rotate about the plurality of coils,
 - a plurality of magnets fixedly coupled to the support ring and positioned proximal to the first circumferential slot, the plurality of magnets having a polarity orientated to redirect flux forces back into the first partial toroidal magnetically closed cylinder.
2. The DC generator/motor of claim 1, wherein the first partial toroidal magnetically closed cylinder has an arc length about the longitudinal axis of greater than 180 degrees.

22

3. The DC generator/motor of claim 1, wherein flux forces generated by the first partial toroidal magnetically closed cylinder flow from interior faces of the first partial toroidal magnetically closed cylinder towards the sectional center of the first partial toroidal magnetically closed cylinder, then flow in a direction generally parallel to the first portion of the a circular rotation path of the first partial toroidal magnetically closed cylinder.
4. The DC generator/motor of claim 1, wherein the plurality of magnets fixedly coupled to the support ring are positioned on both sides of the support ring.
5. The DC generator/motor of claim 1, wherein the plurality of magnets fixedly coupled to the support ring are positioned along a center axis of the support ring.
6. The DC generator/motor of claim 1, further comprising a ring core coupled to the support ring and the plurality of coils such that each coil in the plurality of coils surround a portion of the core.
7. The DC generator/motor of claim 1, wherein the housing is made from back iron material.
8. The DC generator/motor of claim 1, wherein a space circumferentially adjacent to the first partial toroidal magnetically closed cylinder forms a throat.
9. The DC generator/motor of claim 8, wherein a second partial toroidal magnetically closed cylinder is positioned within the throat.
10. The DC generator/motor of claim 8, wherein a partial toroidal nonmagnetic cylinder is positioned within the throat.
11. A generator/motor, comprising:
 - a housing;
 - a rotor, comprising
 - a first partial toroidal magnetically closed cylinder comprising
 - a first partial cylindrical magnetic wall positioned about a longitudinal axis and having a first end and a first opposing end,
 - a first partial opposing cylindrical magnetic wall positioned at a predetermined radial distance from the first partial cylindrical magnetic wall, having a second end and a second opposing end and having a first circumferential slot defined therein,
 - a first magnetic side wall portion spanning from the first end to the second end, and
 - a first opposing side wall portion positioned at a longitudinal distance from the first magnetic side wall and spanning from the first opposing end to the second opposing end,
 - wherein the first partial cylindrical magnetic wall, the first opposing partial magnetic cylindrical wall, the first side wall portion, and the first opposing side wall portion each have a surface and a corresponding magnetic pole of a first polarity that points towards an interior of the first partial toroidal magnetically closed cylinder;
 - a second partial toroidal magnetically closed cylinder comprising
 - a second partial cylindrical magnetic wall positioned about the longitudinal axis and having a third end and a third opposing end,
 - a second opposing partial cylindrical magnetic wall positioned at a predetermined radial distance from the second partial cylindrical magnetic wall, having a fourth end and a fourth opposing end and having a second circumferential slot defined therein,
 - a second magnetic side wall portion spanning from the third end to the fourth end, and

23

a second opposing side wall portion positioned at the longitudinal distance from the second magnetic side wall and spanning from the third opposing end to the fourth opposing end,

wherein the second partial cylindrical magnetic wall, the second opposing partial magnetic cylindrical wall, the second side wall portion, and the second opposing side wall portion each have a surface and a corresponding magnetic pole of a second polarity that points away from an interior of the second partial toroidal magnetically closed cylinder;

wherein the first partial toroidal magnetically closed cylinder has an arc length about the longitudinal axis of greater than 180 degrees and the second partial toroidal magnetically closed cylinder has an arc length about the longitudinal axis of less than 180 degrees;

a center shaft positioned along the longitudinal axis and coupled to the rotor;

a stator comprising

a support ring coupled to the housing and positioned about the longitudinal axis such that a portion of the support ring is within the first circumferential slot and the second circumferential slot;

a center core positioned about the longitudinal axis and coupled to the support ring;

a plurality of coils coupled to the center core and positioned radially about the longitudinal axis such that the first partial toroidal magnetically closed cylinder and second partial toroidal magnetically closed cylinder can rotate about the longitudinal axis along a circular rotation path with respect to the plurality of coils.

24

12. The generator/motor of claim 11, further comprising a plurality of magnets fixedly coupled to the support ring and positioned proximal to the first circumferential slot or the second circumferential slot, the plurality of magnets having a polarity orientated to redirect flux forces flowing back into either the first partial toroidal magnetically closed cylinder or the second partial toroidal magnetically closed cylinder.

13. The generator/motor of claim 12, wherein the plurality of magnets fixedly coupled to the support ring are positioned on both sides of the support ring.

14. The DC generator/motor of claim 11, wherein flux forces generated by the first partial toroidal magnetically closed cylinder flow from interior faces of the first partial toroidal magnetically closed cylinder towards the interior of the first partial toroidal magnetically closed cylinder, then flow in a direction generally parallel to the circular rotation path.

15. The generator/motor of claim 11, wherein flux forces generated by the second partial toroidal magnetically closed cylinder flow from interior faces of the partial toroidal magnetically closed cylinder towards the interior of the second partial toroidal magnetically closed cylinder, then flow in a direction generally parallel to the circular rotation path.

16. The generator/motor of claim 11, further comprising a connecting hub coupling the first partial toroidal magnetically closed cylinder and the second partial toroidal magnetically closed cylinder to the center shaft.
